# ABSTRACT

Objective: To investigate the burden of pedestrian injuries, including pedestrian fall injuries (PFI), compared to other transport-related injuries in Sweden and document their characteristics in terms of demographics, causes, type of injuries, and severity level with a focus on long-term consequences. Methods: Data were retrieved from the national Swedish Traffic Accident Data Acquisition register. A total of 361,531 fatalities and injuries were reported by emergency hospitals during 2010-2019, of which 127,804 were pedestrians (35%). We assessed the magnitude of PFIs and conducted comparative analyses to assess differences compared to other types of road users regarding sex, age, severity level, injury circumstances, hospital care, causes of accidents, and type of injuries. Results: Pedestrians were the second largest group of traffic-related deaths in Sweden after car occupants and accounted for just over a quarter of all fatal accidents in the road traffic environment. Of the total number of pedestrian fatalities, three out of four have been in collision accidents and the others in fall-related accidents. In terms of injuries, pedestrians were the largest group among all road users, regardless of the type of accident. PFIs accounted for a third of all injuries in the road traffic environment and nearly half of all injuries resulting in permanent medical impairment (i.e., 2.2 times more long-term consequences among PFIs compared to injured car occupants). Females (particularly middle-aged and older) and older adults were overrepresented, and most PFIs occurred on urban and municipal roads. The causes were often related to maintenance (e.g., slippery surfaces such as ice, snow, leaves or gravel together with uneven pavements and roads are the cause three out of four of PFIs). Among collision injuries, the representation was almost equal for sex and age. Conclusions: Injuries and fatalities among pedestrians are a considerable issue in the road traffic environment in Sweden. Contrary to other traffic groups, the incidence has not decreased over time, meaning that this issue must be met with specific measures and address the specific risk factors they are associated with. Practical Application: Including fall accidents in the definition of traffic accidents increases the chances of getting better information about the accidents and taking preventive measures. © 2022 The Authors. # 1. Introduction

Although the rates of road traffic fatalities and injuries have declined over the past decade in some continents, the problem continues to increase from a global perspective. Annually, approximately 1.35 million people die and up to 50 million people are injured as a result of a traffic accident in the world (WHO, 2018).

E-mail address: khabat.amin@transportstyrelsen.se (K. Amin).

Road traffic accidents also account for considerable socio-economic costs in terms of medical expenses and lost production, with costs estimated at 0.4–4.1% of Gross Domestic Product (GDP) in European countries (IRTAD, 2019; Wijnen et al., 2019). As such and as a complement to the UN Sustainable Development Goals (SDG) 3.6 in Agenda 2030, a newly adopted resolution from 2020 UN General Assembly, proclaims a new goal of reducing fatalities and injuries by at least 50% between 2021–2030 (UN, 2020a). In Sweden, the ambition has been greater following the 1997 adoption of a Vision Zero policy regarding fatalities and serious injuries in the road traffic environment. However, while the strategy may

st Corresponding author at: Swedish Transport Agency, Department of Roads and Railways, Sweden.

have contributed to a reduction in the number of fatalities among motor-vehicle accidents (Belin et al., 2012; IRTAD, 2019; Tingvall & Haworth, 1999), the same development cannot be observed among *Vulnerable Road Users (VRU)* (IRTAD, 2019; Värnild et al., 2019; Weijermars et al., 2018; WHO, 2018).

VRUs, as defined by the Intelligent Transport Systems Directive (EU, 2010), have recently been recognized by the World Health Organization (WHO) as a particularly important risk group, as they account for more than half of all fatalities in road traffic worldwide (WHO, 2018). Despite being considered to be one of the prioritized groups in the SDGs of Agenda 2030, some incidents are neglected according to the current general definition of traffic accidents (that requires that at least one vehicle in motion on public roads is included in the incident; Eurostat, 2019). As such, incidents where no other road user was involved and that lead to injury or death are excluded, for example pedestrian falls in the road traffic environment.

Despite not being included in some definitions, there are indications that pedestrian fall injuries (PFIs) account for a considerable number of injuries and fatalities that occur in the road traffic environment (Eurostat, 2019; Methorst et al., 2017; Naci et al., 2009). In Sweden, the authority appointed to lead the road safety work has chosen to include single fall injuries that occur in road environment into the national target adopted by the government. The target is to halve the fatalities and reduce injuries with long-term consequences by at least 25% (Swedish Government, 2020).

To properly prioritize road safety measures, it is important to understand the magnitude and characteristics of the problem. To our knowledge, existing studies on PFIs focus on limited samples in terms of age and location, only study outdoor falls without explicitly focusing on the traffic environment, or do not contextualize PFIs compared to injury events for other types of road users (Björnstig et al., 1997; Duckham, Procter-Gray, & Hannan, 2013; Elvik & Bjørnskau, 2019; Gyllencreutz et al., 2015; Lai et al., 2011; Li et al., 2014; Morency et al., 2012; Naumann et al., 2011; Oxley et al., 2018). Importantly, there are also no studies that describe the outcomes of pedestrian falls in terms of the risk of long-term consequenes (i.e., impairment risk). Given that most PFIs are nonfatal, injury measures based on impairment risk are important complements to fatal injury risk.

The aim of this paper is therefore to investigate and contextualize the burden of pedestrian injuries with fatal or long-term consequences from a Swedish perspective. We address limitations from previous work by using national register data and a contextually relevant definition of long-term injuries according to the national targets in Sweden (to halve the fatalities and reduce serious injuries with long-term consequences by at least 25% (Swedish Government, 2020)). Specifically, we document the magnitude and characteristics of pedestrian injuries, including falls, in terms of demographics, trends, causes, type of injuries, and severity level compared to other types of road users to provide a better basis for priority setting.

# 2. Materials and methods

# 2.1. Data collection

# 2.1.1. STRADA – A national road traffic injury register

This study is based on register data derived from the *Swedish Traffic Accident Data Acquisition* (STRADA), a national information system containing data on traffic accidents and injuries occurring in the Swedish road transport system (for a more comprehensive description of STRADA, see <u>Howard & Linder</u>, 2014)). STRADA contains information regarding accidents based on two separate

sources; traffic accident reports provided by the police and medical reports provided by the emergency hospitals. The information contained in the register is pseudonymized (Transportstyrelsen, 2020). This study focuses on hospital data, as this is the only source that includes both the magnitude and severity of injuries. An alternative data source could have been the Swedish National Patient Register that is generally regarded as both valid and reliable (Ludvigsson et al., 2011). However, it has some limitations such as an inability to distinguish between indoor and outdoor cases. Also, there is rarely information about whether the incident occurred in a traffic environment.

Our study focuses on the period 2010 to 2019. Data were limited to this period due to some problems in undercoverage prior to 2010. Fig. 1 shows a flow chart of the number of registered incidents in STRADA, in relation to type of road user, during the timeperiod. In total, there were 640,578 registered incidents during the 10-year period. Of these, 11,886 were excluded as the incidents occurred outside the road traffic environment (in STRADA, the road traffic environment is defined as a street/road, pedestrian and cycle path, sidewalk, separate car park, market square, public transport stop, or petrol station). About one fifth (141,167) of the incidents involved no injuries or an unknown degree of injury. These were also removed. As such, the total number of fatalities and injuries in the road traffic environment between 2010 and 2019 was 487,525. Of these, 361,531 road traffic injuries or fatalities were reported by the emergency hospitals and hence included in our study because PFI is not reported at all by the police. In terms of pedestrians, 125,283 incidents were registered (after excluding road users who had traveled on skateboards, scooters, inline skates, all types of wheelchairs, or horses).

# 2.1.2. Coverage

The number of STRADA-affiliated hospitals gradually increased during the study period from 56 of 71 hospitals in 2010 (corresponding to 82% of the population of the catchment area with 9,340,682 inhabitants) to 73 of 74 hospitals in 2015 (corresponding to 97% of the population of the catchment area of 9,851,017 inhabitants). As of 2016, all emergency hospitals in Sweden that have an emergency department and have either an operation or an orthopedic department report to the register. Since 2018, emergency hospitals no longer report deaths to STRADA and therefore we have limited the analysis of deaths to the period 2010–2017.

# 2.1.3. Measurements

In STRADA, several different metrics are used to quantify injury severity. In terms of fatalities, these are defined as a death that occurred within 30 days from the date of the incident. The cause of death must be related to the injuries sustained in the accident, as decided by the responsible doctor.

In the case of injuries, their severity is quantified in two different ways to capture two important perspectives: (a) the risk of permanent medical impairment (long-term consequences), and (b) the severity of the injury in terms of the acute risk of dying (initial outcomes). The risk of long-term consequences is captured by assessing the measure Risk of Permanent Medical Impairment (RPMI). This measure has been developed to estimate the risk for a patient of suffering a medical impairment at a specific level 1–3 years after the accident, based on the body part and the severity from the AIS classification of injuries using the method described by Malm et al. (2008). The RPMI metric has been validated in relation to sick leave and perceived quality of life (Elrud et al., 2019; Stigson et al., 2020). The Swedish Transport Administration defines a serious injury in the road traffic environment as an injury that leads to a PMI of above 1% (PMI1+) and a very serious injury as an injury that leads to a PMI of above 10% (PMI10+)

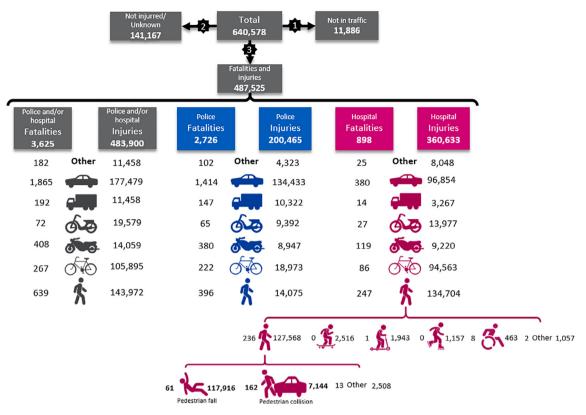

Fig. 1. Number of fatalities and injured by road user category, 2010-2019, STRADA.

(Trafikverket, 2020). The acute risk of dying is captured by the emergency hospitals' injury reporting according to the *Abbreviated Injury Scale (AIS2005, update 2008; AAAM, 2020)*. This study includes road users who died or were injured with at least one injury classified as AIS 1 or higher. Given that a person often has more than one injury, the most severe injury is defined according to the *Maximum AIS (MAIS)* (Decker et al., 2016). For the classification of multiple injuries, a weighting according to the *Injury Severity Score (ISS)* was used, which is an estimate of the probability of death (Baker et al., 1974). However, this measurement does not capture the assessment of medical impairment.

Finally, STRADA also contains a number of characteristics in addition to measures of injury, such as information regarding sex, age, location, circumstances, and so forth. This information is also included in the study in order to compare injury characteristics between types of road users.

# 2.2. Statistical analysis

In order to describe and compare the characteristics of PFIs with other road users, two types of analyses were conducted. First, we analyzed the magnitude of PFIs per 100,000 person-years as well as the characteristics of PFIs in terms of causes, type of injuries, severity level, and comparisons with other types of road users. Secondly, we compared individual- and event-specific characteristics. For the comparison of fatalities and injuries between the groups, one-way analyses of variance (ANOVA) with Bonferroni post-hoc test was used for continuous measurements and Chi-Square with z-test for categorical measurements. Since there are many pairwise comparisons, the p-values were adjusted using the Bonferroni method. An alpha level set at p < 0.05 was considered statistically significant. Rates of injury and fatality are presented per 100,000 person-years. IBM SPSS (version 27) was used for the analysis.

# 2.3. Ethical considerations

This study was approved by the Regional Ethics Board in Uppsala (DNR 2018/480; with addendum [DNR 2021–10338] approved by the Swedish Ethical Review Authority).

# 3. Results

As shown in Fig. 2, the number of PFIs has not declined during the study period, in similarity to cyclists. Decreasing trends are seen amongst car occupants and other types of road users such as motorcyclists, moped drivers, or those who travel by truck or bus.

# 3.1. Fatalities

During the study period (2010–2017), 898 persons were reported by hospitals as fatally injured in the road traffic environment in Sweden (i.e., an average of 112 persons per year; 1,2 per 100,000 person-years). In total, pedestrians were the second largest group after car occupants with 25% of all fatalities. On average, about 8 pedestrians (27% of the pedestrians in total) died annually in falls and 20 in collisions (73% of the pedestrians; Fig. 3).

# 3.2. Injury severity

On average, regardless of the degree of injury, more than 36,000 people were injured annually in Sweden during the period 2010–2019 (367 per 100,000 person-years). The largest group were pedestrians with an annual average of 127 pedestrians per 100,000 person-years. Of these, almost all (94%) were PFIs. Seventeen times more pedestrians were injured in fall accidents than in collisions accidents.

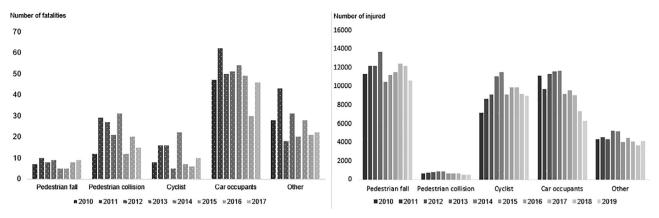

Fig. 2. Number of fatalities and injured by road user category and year. More detailed documentation can be found in Appendix 1.

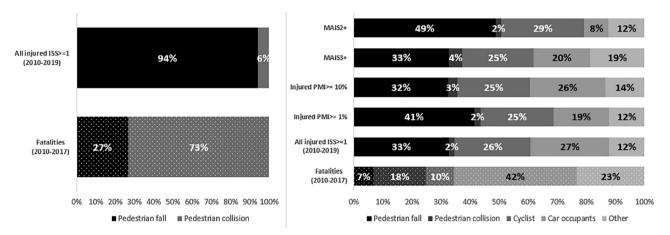

Fig. 3. Proportion of fatalities (2010-2017) and injured (2010-2019) by degree of injuries and road users category.

The distribution between different types of road users and injury severity is presented in Fig. 3. Pedestrians in total (excluding those who travelled on skateboards, scooters, and wheelchairs) accounted for more than a third of the injured (35%). Together with cyclists (26%), the two VRUs categories accounted for almost two-thirds of all injuries in the road traffic environment. Pedestrians also accounted for the largest proportion (43%) of all injured road users with long-term consequences (PMI1+). There were significantly more PFIs with long-term consequences compared to other road users (19 times compared to pedestrian collisions, 1.7 times compared to cyclists and 2.2 times compared to car occupants).

Table 1 shows that every fourth PFI and every fifth pedestrian in collision accidents led to a permanent reduction in PMI1+. For injuries that led to more severe impairment (PMI10+), a significantly higher proportion was seen among pedestrians in collisions compared with other types of road users. In terms of serious initial outcomes (MAIS2+), pedestrians accounted for more than half (51%) of all injuries in the road traffic environment.

# 3.3. Distribution by sex and age

In terms of individual characteristics, males were clearly overrepresented in all catagories, apart from fatal pedestrian collisions where the sex distribution was more equal (Fig. 4). The majority of pedestrian fatalities were males (58%) and 59% were 65 years or older, regardless of sex. The proportion of persons 65 years or older was greater among pedestrians who died in falls (82%).

The proportion of females among injured pedestrians is considerable (69%), not least compared to other types of road users where males generally constitute the large proportion.

The age distribution was also skewed, with 40% of those injured in falls being 65 years or older, regardless of sex. For injured pedestrians in collision accidents, the distribution was more even. Generally, there were considerable differences in the age distribution between injured road users. Fall injuries were more common among the older population, while injuries in bicycle and car accident were more common among the younger population.

# 3.4. Injury circumstances

As is seen in Table 1, the majority of pedestrians injured in falls suffered an injury in an urban area and on a municipal road. Injuries that occurred during leisure time were common regardless of the type of road user but more common among PFIs. The cause of PFIs varied greatly during the year. Injuries due to slippery surfaces such as ice, snow, or gravel were more common (60%) among PFIs compared to other types of road users. Most pedestrian injuries (77%) occurred during the cold season in Sweden (November 1 to April 30), with an average of 91 injured per 100,000 personyears. On a yearly basis, more than half of all pedestrians were injured in falls due to slips. However, the proportion was significantly greater (73%) during the winter season. The proportion who were injured during the autumn (September 1-November 30), when daylight hours are fewer, was greatest among pedestrian collisions (30%) compared with other types of road users.

# 3.5. Hospital care

Most PFIs (84%) left the hospital after treatment at the emergency department (i.e., they were not admitted). However, about

**Table 1**Number and proportion of fatalities during study period 2010–2017 and injured 2010–2019 after each road user category and characteristic information.

Each subscript letter represents a subset of the road user category whose column proportions do not differ significantly from each other at the 0.05 level. That is, those with the same letter do not have a difference, but those with different letters have a statistically significant difference.

16% were hospitalized and the average length of care was almost five days. In total, PFIs who were admitted to hospital stayed for almost 75,000 days during the study period. The proportion of people admitted to the hospital was higher among pedestrians in collision accidents compared to other road users. On average, they remained in hospital for almost a week.

# 3.6. Injury type

On average, pedestrians sustained 2.4 injuries after a collision and 1.4 injuries after a fall. Fig. 5 illustrates that, regardless of severity, injuries to the upper extremity such as wrist, shoulder, and elbow were more common among PFIs (42%). The most com-

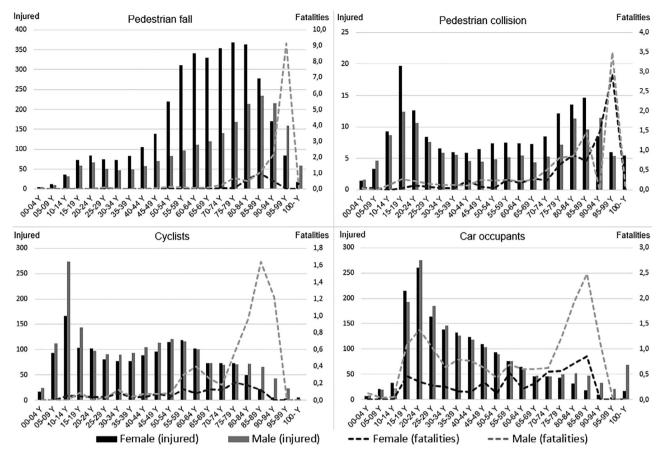

Fig. 4. Number of fatalities (2010-2017) and injured (2010-2019) per 100,000 person-year, age group, and road user category.

mon type of injury among pedestrians in collision accidents were superficial wounds (72%) followed by fractures of the hip, knee and leg (28%). Head injuries were significantly more common among injured pedestrians in collision accidents (13%) compared to other road users (see Appendix 1).

As shown in Fig. 6, 53% of pedestrians in fall accidents with long-term consequences (PMI1% +) had injuries to the upper extremity such as hand, arm, or shoulder. Half of the pedestrians (51%) in collision accidents with long-term consequences (PMI1% +) suffered an injury to the lower extremities such as knee or hip. Head injuries, both initially (Appendix 2) and as a long-term consequence (Fig. 6), were significantly more common among pedestrians in collisions compared to other road users categories.

# 4. Discussion

In spite of VRUs being the most common traffic injury and entailing a high cost for society, traditional traffic safety work tends to focus on injured motorists or VRUs in collision with motorists. One potential reason for the lack of interest in PFIs is the lack of a consistent and clear definition of fall accidents in the road traffic environment. The fact that a vehicle must be involved in a collision in order for it to be counted as a road traffic accident (Eurostat, 2019) has inadvertently eliminated PFIs from official statistics. In turn, this may have led to the responsibility for pedestrian traffic falling between several instances, with no one taking overall responsibility. In order to overcome this and reduce injuries with long-term medical consequences and fatalities, a clear definition of pedestrian accidents and injuries in the road traffic environment is required as well as high-quality data.

In this first nationwide scientific study on accidents in the road traffic environment among pedestrians, with a focus on PFIs and their relation to other road user categories, we find that during 2010-2019, over 125,000 individuals (128/100,000 person-years) died or required emergency medical treatment. Whether this number or rate is high or not is difficult to assess as there are few comparable studies. Specifically, previous studies are limited in terms of age, location, studying all falls outdoors, or without comparing to other road user categories (Björnstig et al., 1997; Duckham, Procter-Gray, & Hannan, 2013; Elvik & Bjørnskau, 2019; Li et al., 2014; Morency et al., 2012; Naumann et al., 2011; Oxley et al., 2018). However, regardless, pedestrians now account for the second largest group of traffic-related deaths in Sweden, with higher rates among pedestrians in collisions compared to fall accidents. Similarly, in terms of injuries, pedestrians are the largest group among all road users injured in the road traffic environment, regardless of the degree of injury, a result similar to previously reported studies (Ahnlund, 2008; Methorst et al., 2017).

Perhaps most importantly, every fourth PFI leads to permanent disability according to the injury measure PMI 1%. The proportion is even higher according to MAIS, where more than half receive injuries with MAIS 2+. Diagnoses leading to impairment differ to some extent from injuries classified as AIS2+ or AIS3+. There is a particular need to consider certain diagnoses which lead relatively often to long-term consequences at AIS1 level degrees from injuries. VRUs in urban areas, including PFIs, are found at lowered thresholds for injury or impairment levels compared to vehicle occupants. In addition, there are diagnoses that more rarely lead to impairment among higher levels of AIS (Tingvall et al., 2013). Among the more severe injury outcomes, both initial outcomes (MAIS33+) and long-term consequences (PMI10+), pedestrians in

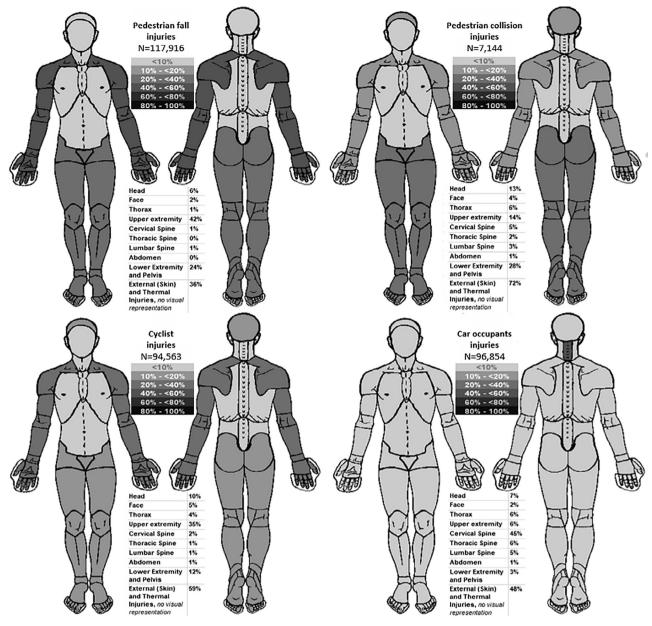

Fig. 5. The proportion of injuries after road users category and body part, 2010–2019). A person can have injuries to several body parts,

motor-vehicle collisions were a more affected group than PFIs, which is not surprising given the larger amount of energy in the incident. However, although they are more affected, our study shows that PFIs are up to 17 times more common than pedestrian injuries due to collisions, regardless of the degree of injury. This is significantly higher than the results shown in previous studies (Methorst et al., 2017). The difference between the two studies may indicate the success of road safety measures for VRUs such as vehicle improvements and the road traffic environment combined with lower speeds in urban areas, thereby reducing the number of collisions (Ballesteros et al., 2004; Oxley et al., 2013; Strandroth et al., 2011).

Our results show that, on average, pedestrians suffered more injuries in collision accidents than in falls, in accordance with other studies (Hu & Klinich, 2014). While injuries most commonly occurred to the upper extremities, hip and lower extremities were also common. Although hip fractures are generally not defined as a serious injury, from a long- to medium-term perspective they have

a high mortality rate within one year after a fracture (Mellner et al., 2020). Also, they lead to serious consequences such as poor health and loss of life activities (LeBlanc et al., 2011; Lyles et al., 2007). As such, these injuries should also be taken seriously. In relation to other road users, head injuries among pedestrians in collision accidents led to more long-term consequences (PMI1+), a result supported by Fredriksson, Rosén, and Kullgren (2010).

In terms of sex and age, pedestrian morbidity and mortality differ considerably to other traffic-related incidents. Traditionally, males are overrepresented in traffic-related morbidity and mortality, however, amongst pedestrians, females are overrepresented. Also, in PFIs, those 65 years or older are clearly overrepresented. Previous studies have shown that the risk of falls increases with age, especially for females (Elvik & Bjørnskau, 2019; Gyllencreutz et al., 2015; Morency et al., 2012; Naumann et al., 2011). Given the projected increase in the percentage of elderly people in the population of high-income countries (OECD, 2003), this clearly shows the importance of this issue for countries in similar

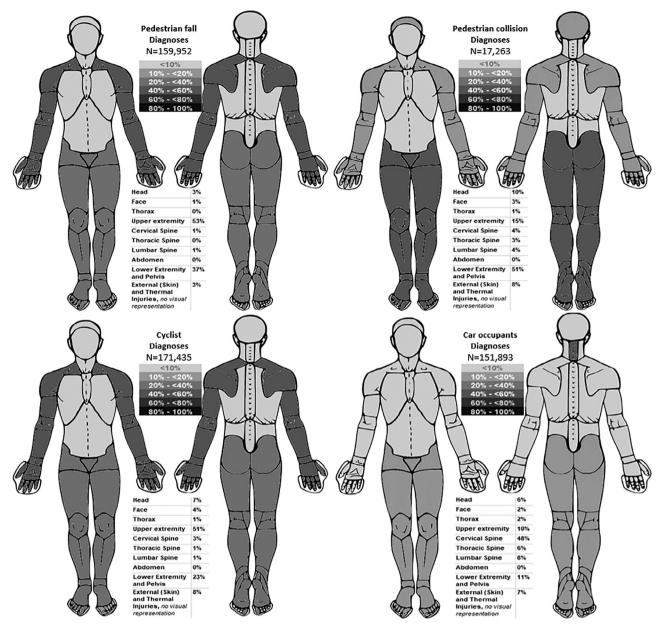

Fig. 6. The proportion of diagnoses leading to PMI1 + after road users category and body part, 2010-2019). A person can have injuries to several body parts.

demographic situations. The significantly older age amongst injured pedestrians, compared to other road users, is problematic when comparing risk. Ideally, time- or distance-related risk measurements would be used when comparing morbidity or mortality rates. However, the knowledge regarding pedestrians' time or distance spent travelling is limited and underreported, not least with regards to age (Sammer et al., 2018). This element needs to be studied further as are factors related to increased knowledge about which groups can be affected by fall accidents. Variables such as gender, ethnicity, class, and disability would provide additional dimensions to the consequences of fall accidents.

Given the results in this study, it is clear that the current definition regarding which accidents are included in the definition of road traffic accidents should perhaps be reassessed. The current definition, based on the Vienna Convention on Road Traffic from 1968, was formulated at a time when collision- and motorvehicle-related accidents dominated the traffic-related injury and fatality panorama. However, the situation is now very different

and, as such, we would argue that PFIs should now be defined as pedestrians who fall in public spaces outdoors without colliding with other road users, in accordance with Methorst (2021). This would include these incidents in the official statistics and thereby adhere to Objective 11 of the Sustainable Development Goals, entailing that by 2030, people will have access to safe, affordable, accessible, and sustainable transport systems (UN, 2020b). By taking such a holistic view and including PFIs in the official statistics, more targeted measures may be needed and developed in order to reduce injuries among VRUs.

In terms of interventions, a systematic review of multifaceted interventions (e.g., information, education, environmental modification, and personal protection such as safe footwear) at the population level showed reductions in fall-related injuries between 6% and 75% (McClure et al., 2005). Also, urban planning, where the road system is adapted to human abilities and limitations (Schepers et al., 2017), can reduce rates (e.g., through the International Road Assessment Program (iRAP) which could be important

to introduce; WHO, 2018). From a maintenance perspective, slipping on leaves, gravel, etc., are important aspects to address (Lai et al., 2011) and this study suggests that slippery surfaces such as ice, snow, leaves, or gravel together with uneven pavements and roads are the cause of three out of four PFIs.

The risk of ice or snow in snow-rich countries has been reported previously (Bergland et al., 2003; Duckham, Procter-Gray, Hannan, et al., 2013; Elvik & Bjørnskau, 2019; Gyllencreutz et al., 2015; Morency et al., 2012; Pajala et al., 2008) and requires specific interventions. Studies have shown that the risk of being injured as a pedestrian in winter is as low as in summer if winter conditions such as ice and snow are eliminated (Elvik et al., 2019), and the individual-level anti-slip devices (e.g., ice cleats) can reduce the risk of PFIs and increase the amount of walking (Berggård & Johansson, 2010; McClure et al., 2005; McKiernan, 2005). From a societal perspective, the spread of hot sand (Niska, 2013), distribution of ice cleats to older adults (Bonander & Holmberg, 2019), or ground heating of roads and sidewalks (thereby reducing ice and snow by 60%; Öberg et al., 1998; Öberg, 2011), are interesting alternatives that should be investigated further.

Strengths and limitations

To our knowledge, this paper is the first to report on the magnitude and characteristics of PFIs on a national level and compare these injuries to other types of road users over several years. The STRADA register offers a unique opportunity to study this problem using data reported by every emergency hospital in Sweden. The register data contains detailed information on the characteristics and severity of injuries from a large number of injury events (n = 361,531), and should represent an almost complete account of traffic injury events that occurred in Sweden between 2010 to 2019 that have come to the attention of emergency departments. While we have mentioned that there was some undercoverage during the first few years included in our analysis, it is important to keep in mind that there may be additional measurement errors present in the data. For instance, some injured individuals may not seek treatment and some events may not have been reported to STRADA because of, for example, shortages in hospital staff.

An additional limitation to our study is that the results are specific to Swedish conditions. The results – especially those related to falls due to slippery road conditions – may not be generalizable to countries located in warmer regions. While we expect

that the results should be generalizable to countries with a similar road traffic environment and climate, it would be of considerable interest to see how well our results can be reproduced in other countries.

# 5. Conclusion

Pedestrians are a large vulnerable group in the road traffic environment. Despite this, the knowledge regarding injuries to this group is largely unknown as PFIs are not included in the official statistics on road traffic injuries. Contrary to other traffic groups, injuries and fatalities have not decreased, meaning that they must be met with measures that specifically address the risk factors they are associated with, such as age and slipping on gravel, leaves, snow, etc. on streets and sidewalks in urban areas. Focusing only on classic approaches that work for vehicle-related accidents seems to be ineffective for VRUs and therefore new strategies are required.

**Khabat Amin** is a Ph.D. student at the Centre for Societal Risk Research at Karlstad University. His research area is road safety for pedestrians. He also works at the

Swedish Transport Agency as a statistician and analyst, mainly with road traffic accident data.

**Marie Skyving**, analyst at the Swedish Transport Agency have a background in Public Health Science and have been in the field of injury prevention and road safety since 2005. She is currently writing a doctoral thesis on the topic health conditions in older drivers and risk of road traffic crash at Karolinska Institutet.

**Carl Bonander** is an associate professor of epidemiology in the School of Public Health & Community Medicine at the University of Gothenburg. His research interests include evaluation of health interventions in societal contexts, as well as methodological development to improve the validity of population-based research.

**Finn Nilson** is an associate professor of Risk Management with a focus on injury prevention and societal safety. He is also the co-director of the Centre for Societal Risk Research at Karlstad University, Sweden. His research concerns injury prevention epidemiology and evaluation of interventions with a special interest in underlying sociodemographic risk factors.

**Maria Krafft** is an associate professor of experimental surgery with focus on traffic medicine at Umeå University, Sweden. Since 2015 Krafft is director of Traffic Safety at the Swedish Transport Administration. The research is primarily based on crashworthiness analysis and its health consequences.
